

## Transformation Unit NOTES

A function transformation takes the basic parent function  $f(x)$  and then "transforms" it or "translates" it, which is a fancy way of saying that you change the equation a bit and it moves the graph around.

### Basic Transformations:

ALL basic transformations of functions follow these rules:

#### Translations ("shifts")

- $f(x) + k$  is  $f(x)$  shifted upward  $k$  units
- $f(x) - k$  is  $f(x)$  shifted downward  $k$  units
- $f(x + h)$  is  $f(x)$  shifted left  $h$  units
- $f(x - h)$  is  $f(x)$  shifted right  $h$  units

#### Reflections ("flips")

- $-f(x)$  is  $f(x)$  flipped upside down ("reflected about the  $x$ -axis")
- $f(-x)$  is the mirror of  $f(x)$  ("reflected about the  $y$ -axis")

### Additional Transformations:

There are additional transformations called dilations and compressions, but it is a bit harder to see these changes. If you compare the graphs of  $2x^2$ ,  $x^2$ , and  $\frac{1}{2}x^2$ , you'll see that the graph doesn't change its position as much as its size. The parabola for  $2x^2$  "grows" twice as fast as  $x^2$ , so its graph is tall and narrow, which is "stretching" it away from the  $x$ -axis (dilation). The parabola for the function  $\frac{1}{2}x^2$  "grows" only half as fast, so its graph is short and wide, which "compresses" it toward the  $x$ -axis. So, multiplying the function by a number in front changes the distance of the graph from the  $x$ -axis, by stretching it or compressing the picture.

Now compare the graphs of  $(2x)^2$ ,  $x^2$ , and  $(\frac{1}{2}x)^2$ . The parabola for  $(2x)^2$  is "compressed" toward the  $y$ -axis, and "stretched" away from the  $y$ -axis for  $(\frac{1}{2}x)^2$ . So, multiplying the  $x$  by a number "inside" the function (or parentheses, in this case) changes the distance of the graph from the  $y$ -axis, by stretching it or compressing the picture.

## Dilations / Compressions

- $a \cdot f(x)$  is a vertical transformation of the graph of  $f(x)$ , with a “stretch” or “dilation” if  $a > 1$ , and a “compression” if  $a < 1$ .)
- $f(a \cdot x)$  is a horizontal transformation of the graph of  $f(x)$ , with a “stretch” or “dilation” if  $a < 1$ , and a “compression” if  $a > 1$ .

## Formula for Putting it All Together

let  $g(x)$  be a transformation of some function  $f(x)$

$$\begin{array}{c} \text{horizontal} \\ \text{transformation} \\ \downarrow \\ \mathbf{g(x) = a(bx - h) + k} \\ \begin{array}{ccc} \uparrow & \uparrow & \uparrow \\ \text{vertical} & \text{horizontal} & \text{vertical} \\ \text{transformation} & \text{shift} & \text{shift} \\ \text{\& reflect over } x & & \end{array} \end{array}$$

**Practice:** name the parent function, and describe the changes:

$$f(x) = -3(x - 2)^2 + 5$$

---

---

---

$$f(x) = |x - 3| - 2$$

---

---

---

$$g(x) = \frac{1}{x} + 1$$

---

---

---

$$g(x) = -2^x + 1$$

---

---

---
